Quadrilateral vs bilateral
VSP – An alternative option to maintain yield?

Why do Colorado vineyards have such low yields?
Training & re-training

Why do Colorado vineyards have such low yields?

Cold
What contributes to low yields?

- **Cold temperature injury**

But there are also other factors:

- **Management issues**
  - Variety / site selection
  - Vineyard setup
    - (vine x row spacing; trellis / training system)
  - Vine pruning / training
  - Low vine vigour
What contributes to low yields?

• **Cold temperature injury**
  • Damage to fruitful (primary, secondary) buds
  • Loss of cordons / canes
  • Loss of trunks
  • Loss of vines
Management issues

- Variety / site selection
  Cold-sensitive varieties in cold sites

- Vineyard setup
  Small total canopy size per acre:
  - Low vine densities
  - Trellis/training systems
Other factors besides cold that contribute

- Management issues
  - Vine pruning / training
    Pruning too aggressive (low bud number)
    Single-trunk vines
  - Low vine vigour
    Nutrient deficiencies
    Water stress
    Excessive crop load in previous year(s)
    Inappropriate vine spacing
## Vine densities

</tbody>
</table>
Relationship between canopy length & yield

A vineyard with a 10 foot row spacing has 4,356 ft of row (=canopy) length per acre. For a target yield of 4 ton/acre we need to produce 1.84 lb/ft of row:

4,356 ft/acre * 1.84 lb/ft ~ 8,000 lb/acre (5’ x 10’)

At closer row spacings we need less lb/ft for the same per-acre yield as there are more feet of canopy per acre:

5,445 ft/acre * 1.47 lb/ft ~ 8,000 lb/acre (5’ x 8’)

7,260 ft/acre * 1.10 lb/ft ~ 8,000 lb/acre (5’ x 6’)

Colorado State University
Knowledge to Go Places
Scenario: A Syrah vineyard trained to VSP. Vines are cordon-trained and spur-pruned, leaving three 2-bud spurs per foot. Average bunch weight is ¼ lb.

There is no cold injury (100 % bud break of primary buds). Fruitfulness is high, averaging 2 clusters per shoot.

What yield can we expect?
Relationship between canopy length & yield

Three 2-bud spurs per foot produce 6 shoots per foot.

Six shoots per foot produce 12 bunches per foot.

12 bunches * \( \frac{1}{4} \) lb per bunch = 3 lb/ft

3 lb/ft * 4,356 ft/acre = 13,068 lb/acre (~6.5 ton/acre)

3 lb/ft * 5,445 ft/acre = 16,335 lb/acre (~8.2 ton/acre)

3 lb/ft * 7,260 ft/acre = 21,780 lb/acre (~10.9 ton/acre)

But is this realistic?
These are not realistic assumptions:

There is no cold injury

100 % bud break of primary buds

Fruitfulness is high, averaging 2 clusters per shoot

There is 100 % canopy fill within the vineyard
Looking back to all surveys since 2000, Syrah in Mesa County has averaged 2.7 ton/acre, and has never reached an annual average of 4 ton/acre.

At the wide spacing of 5’ x 10’ a yield of 4 ton/acre is only 61.5 % of our theoretical yield.

In other words, even in the best vintages Syrah is at least 40 % below the potential (and this is true for all other varieties).

Why? And how do we change that?
What contributes to low yields?

- Cold temperature injury

- Management issues
  - Variety / site selection
  - Vineyard setup
    (vine x row spacing; trellis / training system)
  - Vine pruning / training
  - Low vine vigour
Which ones are easy to address?

- Cold temperature injury
- Management issues
  - Variety / site selection
  - Vineyard setup
    (vine x row spacing; trellis / training system)
  - Vine pruning / training
  - Low vine vigour
Bi- versus quadrilateral cordon/cane

Bilateral cordon with spur pruning is the standard pruning method in Colorado.

Our observations with bilateral cordon indicate that shoot density is often well below optimum, even when bud damage due to cold injury is taken into consideration prior to pruning.

We are looking for means to increase bud/shoot number per vine other than longer or more spurs on the cordons.
Why not just leave spurs longer and/or leave more spurs on the cordon?
Bi- versus quadrilateral cordon/cane

Long spur, but only one shoot. Also, if cordon is dead, it doesn’t matter how long the spurs are.
In 2011, we started an experiment in two vineyards (one at CSU-WCRC and one with a grower cooperator on Orchard Mesa) to compare the standard bilateral to a quadrilateral system.
Objective

Increase yield via an increase of shoot density (= decrease of canopy gaps).
Two field sites in 2011

- Vineyard A (CSU-WCRC)
  - Syrah
  - Planted in 2001, 5’ x 9’ (968 vines per acre)
  - VSP

- Vineyard B (Grower cooperator)
  - Tempranillo
  - Planted in 2009, 5’ x 2 m (1,328 vines per acre)
  - VSP
Materials and Methods

At site A, a second (higher) cordon wire was added in 2 rows, and an additional two canes/vine were trained to that wire.

At site B, four pairs of rows were selected prior to pruning. For each pair, a second (higher) cordon wire was added to one row, and an additional two canes/vine were trained to that wire.

Fruit was harvested separately from lower and upper wire.
Materials and Methods

Harvest measurements (per row & wire)
- Bunch number
- Yield

Other measurements
- Vine number (per row)
- Number of buds retained (separate for lower & upper wire)
- Number of shoots (separate for lower & upper wire)
- Number of vines used for each treatment (~70 %)

Results – Syrah 2011

The change from bi- to quadrilateral training resulted in

- 74 % more buds
- 89 % more shoots
- 67 % more bunches
- 88 % more yield

In a year when both percentage bud break (42 %) and fruitfulness (1.24 bunches/shoot) was low.

YIELD WAS STILL <4 TON/ACRE
Results – Tempranillo 2011

![Chart showing yield comparison between bilateral and quadrilateral planting.]
Results – Tempranillo 2011

The change from bi- to quadrilateral training resulted in

• 55 % more buds
• 62 % more shoots
• 56 % more bunches
• 41 % more yield

In a year when both percentage bud break (36 %) and fruitfulness (1.28 bunches/shoot) was low.
Bi- versus quadrilateral cordon/cane

The 2011 growing season was unusual.

First, vines are still recovering from the Dec. 2009 cold event.
Second, cold events in early January and again early February resulted in ~30 % dead primary buds.
Third, a late spring freeze (May 1 and 2) led to further bud injury right at the time of bud break.
Combined, this led to very low percentage final bud break (42 % in Syrah; 36 % in Tempranillo) and very low shoot densities with bilateral training (2.1 shoots/ft for Syrah; 2.0 shoots/ft for Tempranillo).
Bi- versus quadrilateral cordon/cane

The 2011 growing season was unusual (cont.)
Hence, almost doubling the number of buds retained after pruning did not cause excessive shoot densities but resulted in shoot densities much closer to the desired values (4 – 6 shoots/ft for non-divided canopies) and a significant yield increase.

In years when bud cold injury is minimal and percentage bud break is high, bud and/or early shoot thinning would be required to avoid excessive shoot densities.

However, in our Syrah block low shoot densities have been the norm – not the exception – and we will continue to evaluate quadri- versus bilateral training with our VSP trellis for at least another 2 years.
Quadrilateral vs bilateral VSP – The second year (2012)

Materials and Methods

Three field sites in 2012

• Vineyard A (CSU-WCRC)
  • Syrah
  • Planted in 2001, 5’ x 9’ (968 vines per acre)
  • VSP

• Vineyard B (Grower Cooperator)
  • Tempranillo
  • Planted in 2009, 5’ x 2 m (1,328 vines per acre)
  • VSP

• Vineyard C (2nd Grower Cooperator)
  • Gewürztraminer
  • Planted in 2007, 5’ x 8’ (1,089 vines per acre)
  • VSP
In 2012, some methodology was changed:

At site B, detailed measurements were made in four (out of 12 panels per row) central panels with yield data collected on entire rows.

At site C, four 6-vine panels in the center of four adjacent rows were selected prior to pruning. Treatments (bi- or quadrilateral) were alternated between panels down rows #5 and #7, with opposing treatments in rows #6 and #4, respectively (paired comparison with 8 reps).

Syrah 2012 versus 2011

Slight increase in nodes retained after pruning.

Almost identical percentage bud break.

Hence, only a slight increase in shoot number per vine.

But a large increase in bunch number per vine, and thus yield, with no changes in mean bunch and berry weights.

How do we explain this large yield increase?
Results – Syrah 2012
Syrah 2012 versus 2011

The primary reason for the much higher yield in 2012 was NOT

Higher bud number / shoot number / percentage bud break

But higher shoot fruitfulness, most likely the outcome of a much higher percentage of primary shoots in 2012.
Quadrilateral cane – Syrah, Dec 2012

</table>
Tempranillo 2012 versus 2011

Minor increase in nodes retained after pruning.

Higher percentage bud break (54 % vs 35 %).

Hence, a large increase in shoot number per vine.

A higher shoot fruitfulness causing a large increase in bunch number per vine (but a decrease in bunch weight).

Yield increase of >2 ton/acre due to both higher percentage bud break and higher shoot fruitfulness.

Colorado State University
Western Colorado Research Center
Grand Junction, CO 81503
Ph: (970) 434-3264
www.colostate.edu/programs/wcrc/Vithome.htm
The 2013 growing season.

A series of extreme cold temperature events occurred in late December 2012 and mid January 2013. Those cold events caused 100% vine dieback to the ground in the Gewürztraminer and Tempranillo blocks, and ~50 vine dieback in the Syrah (lower dieback in the Syrah presumably due to use of wind machine during the events).

So in 2013 we set up a trial with Cabernet Franc. In addition to trunk injuries we found very high bud damage in Syrah (~70% dead fruitful buds) after January, but only minor damage in the Cabernet Franc. However, two late spring freezes are thought to have caused significant bud damage in the Cabernet Franc.
Two field sites in 2013

- Vineyard A (CSU-WCRC)
  - Syrah
  - Planted in 2001, 5’ x 9’ (968 vines per acre)
